## Introduction

What is obfuscation?

Architecture of an LLVM-based obfuscator

## LLVM bitcode obfuscations

### Frankenstein obfuscation

### Improved pass management

### Tests and benchmarks

**Obfuscations** are mainly done on the LLVM **Internal Representation**

Obfuscation = Optimisation = LLVM pass

**Obfuscations** are mainly done on the LLVM **Internal Representation**

### Advantages (in theory)

- ▶ Language-agnostic obfuscations
- ▶ Backend independent obfuscations

### Disadvantages

- ▶ Some CPU-specific tricks can't be implemented in a generic way
- ▶ Some information are not available at IR level (function size, function pointers value, ...)

# Flow of compilation

## Mixing optimisations and obfuscations

- ▶ First rule: obfuscations must *survive* LLVM optimisations
- ▶ Performance is important: run classical LLVM optimisations first
- ▶ Then obfuscations are applied
- ▶ And a post optimisations pass is done

# Flow of compilation

## Mixing optimisations and obfuscations

Trust me, I have a Graph

Tests and benchmarks

# Obfuscate Predicates

Replace constants by computations depending on the context ( $r$ ).

Example:

$$\boxed{42} == (r \mid 58) \& (\sim 5) \& 47$$

## Advantages

- ▶ Can be fully implemented at IR level
- ▶ Is language and backend independant
- ▶ Even works for vectorized operations

# Obfuscate Predicates

Which context value to choose ? x or i ?

```
int x = ... ;  
for(int i = 0; i < n; ++i)  
    s += 42;
```

## Problem of randomness

- ▶ Based on a fixed random-seed to enable reproductibility
- ▶ Unguaranteed performance reproductibility across seeds

# Table of Contents

Introduction

LLVM bitcode obfuscations

Opaque predicates

Control-Flow-Graph Flattening

Dynamic protections

Frankenstein obfuscation

Improved pass management

Tests and benchmarks

# Control-Flow-Graph Flattening

Transform all branches to jumps to a dispatcher with a switch statement:

CFG for 'check' function

# Control-Flow-Graph Flattening

Transform all branches to jumps to a dispatcher with a switch statement:

CFG for 'check' function

# Control-Flow-Graph Flattening

## Windows Exceptions

Windows exceptions impose restrictions on the CFG:

- ▶ Treat blocks with the same parent exception pad as belonging to the same *set*.
- ▶ Invokes, exception-handling pads and exception-handling returns edges are left as they are.
- ▶ Flatten each *set*.

Tests and benchmarks

# Anti-Debug/Jailbreak/Emulator

Check the executable's environment to detect jailbroken devices:

- ▶ Periodic checks injected in the code
- ▶ Startup checks (platform dependent!)
- ▶ Implement the checks in C

```
bool test_jailbreak() {  
    FILE *fp;  
    const char path[] = "/private/random_name";  
    if((fp = fopen(path, "w")) != NULL) {  
        fclose(fp);  
        unlink(path);  
        return true; // detected  
    }  
    return false; // not detected  
}
```

# Anti-Debug/Jailbreak/Emulator

Inserting checks at startup is platform dependant:

## Problem

Windows:

- ▶ LLVM's `global_ctors` priorities are broken on Windows
- ▶ Sections `.CRT$XCA` ... `.CRT$XCZ`
- ▶ TLS constructors, executed for each thread, even before initializing the CRT

# Anti-Debug/Jailbreak/Emulator

Implement the complex checks in C .

## Problem

- ▶ Cannot rely on calls to a library: easy to identify and isolate, and can't be obfuscated by the user
- ▶ Really hard to pre-generate the IR for every target platform

## Solution: *clang-ception*

Compile C code on demand by using clang within clang.

- ▶ Shared resources: LLVMContext (and global variables, ugh!)
- ▶ The user can write its own checks
- ▶ Can easily apply obfuscations on the C code

# Code integrity

On the previous anti-jailbreak test function...

```
bool test_jailbreak() {  
    FILE *fp;  
    const char path[] = "/private/random_name";  
    if((fp = fopen(path, "w")) != NULL) {  
        fclose(fp);  
        unlink(path);  
        return true; // detected  
    }  
    return false; // not detected  
}
```

How to check the function hasn't been modified?

## Goal of code integrity

Verify code wasn't tampered *a priori* / at runtime

# Code integrity checks

## At the binary level

- ▶ One check at startup  $\Rightarrow$  easy to remove
- ▶ Injection at various places  $\Rightarrow$  potential performance issues:
  - ▶ using siphash 1-2 (non-linear *fast* hash)
  - ▶ using an Intel i7-6700HQ CPU:  $\sim 0.7$  cycles per byte
  - ▶ on a 60MiB binary (like clang):  $\sim 44\text{M}$  cycles  $\Rightarrow \sim 20$  ms at 2Ghz

$\Rightarrow$  We also need function-level integrity checks!

# Code integrity checks

## At the binary level

- ▶ One check at startup  $\Rightarrow$  easy to remove
- ▶ Injection at various places  $\Rightarrow$  potential performance issues:
  - ▶ using siphash 1-2 (non-linear *fast* hash)
  - ▶ using an Intel i7-6700HQ CPU:  $\sim 0.7$  cycles per byte
  - ▶ on a 60MiB binary (like clang):  $\sim 44\text{M}$  cycles  $\Rightarrow \sim 20$  ms at 2Ghz

$\Rightarrow$  We also need function-level integrity checks!

## At the function level

- ▶ Hashes each function individually
- ▶ Check hashes at the beginning of each function, before each call sites...
- ▶ Cross check functions between them

# Code integrity: function level

## Basic idea/example

```
void foo() {  
    puts("hello world!");  
}
```

becomes:

```
static unsigned hashes[] = { ... };  
static unsigned hash(void* begin, void* end) { ... }  
void foo() {  
    if (hash(&&begin, &&end) != hashes[foo_id])  
        exit(...);  
begin:  
    puts("hello world!");  
end:  
}
```

# Code integrity: function level

## Basic idea/example

```
void foo() {  
    puts("hello world!");  
}
```

becomes:

```
static unsigned hashes[] = { ... };  
static unsigned hash(void* begin, void* end) { ... }  
void foo() {  
    if (hash(&&begin, &&end) != hashes[foo_id])  
        exit(...);  
begin:  
    puts("hello world!");  
end:  
}
```

## Doing this at IR time: pros

- ▶ Cross-language/platform way to insert the hash function (using *clang-ception*)
- ▶ Easier to insert checks than at backend time

# Code integrity: function level

## Basic idea/example

```
void foo() {  
    puts("hello world!");  
}
```

becomes:

```
static unsigned hashes[] = { ... };  
static unsigned hash(void* begin, void* end) { ... }  
void foo() {  
    if (hash(&&begin, &&end) != hashes[foo_id])  
        exit(...);  
begin:  
    puts("hello world!");  
end:  
}
```

## Doing this at IR time: cons

- ▶ How to get a pointer to the end of a function?
- ▶ Obviously, the assembly code of functions isn't available  
⇒ IR ⇔ backend cooperation!

# Issue with end-of-function

## The problem

No object in the LLVM IR is associated with the *end* of a function

## A solution...

# Issue with end-of-function

## The problem

No object in the LLVM IR is associated with the *end* of a function

## A solution...

`llvm::BlockAddress` to the rescue!

- ▶ `llvm::Constant`, lowers to the address of a block within a function.
- ▶ Extension: `blockaddress(null, foo)` as the address of the end label for the `foo` function.
- ▶ Add `endfuncptr` in the LLVM-IR format

Problems:

- ▶ Incompatible modification of the LLVM IR format:
  - ▶ Potential problem for iOS apps!
- ▶ Is a hack...

# IR-backend cooperation

## General idea

- ▶ Put placeholders for function hash values
- ▶ Use a post-processing tool that "fixes" the placeholders

## Issues

- ▶ Need a cross-platform/cross-format (PE,ELF,Mach0) tool (free-ad: LIEF <sup>1</sup> is a good framework for this!)
- ▶ Not trivial to obfuscate hashes values and function pointers

---

<sup>1</sup><https://github.com/quarkslab/LIEF>

# Q<sup>b</sup>Code integrity: remaining problems

## Non exhaustive list of gotcha

- ▶ Dynamic relocations within code
- ▶ Assume function code is contiguous: technically no guarantee in LLVM
- ▶ Relies on undefined behavior: pointer arithmetic and dereferencing a function pointer is UB
- ▶ C function pointer  $\neq$  beginning of function code

# The JIT way

## Idea

Use the LLVM jitter to generate binary code of a function at IR-time

## Benefits

- ▶ A function becomes an array of bytes, treated (almost) as any other data array
- ▶ *Free* integrity checks
- ▶ *Free* on-the-fly decryption/reencryption

## Drawbacks

# The JIT way

## Idea

Use the LLVM jitter to generate binary code of a function at IR-time

## Benefits

- ▶ A function becomes an array of bytes, treated (almost) as any other data array
- ▶ *Free* integrity checks
- ▶ *Free* on-the-fly decryption/reencryption

## Drawbacks

- ▶ Final symbols address unknown at IR-time
- ▶ C++ exception frames to register "by hand"
- ▶ NX-bit protection

# The JIT way

## Idea

Use the LLVM jitter to generate binary code of a function at IR-time

## Benefits

- ▶ A function becomes an array of bytes, treated (almost) as any other data array
- ▶ *Free* integrity checks
- ▶ *Free* on-the-fly decryption/reencryption

## Drawbacks

- ▶ Final symbols address unknown at IR-time
- ▶ C++ exception frames to register "by hand"
- ▶ NX-bit protection

Hard to make it work in real-life applications!

# To the road of performances...

## Problem

- ▶ Impossible to apply all the obfuscations all the time
- ▶ Locality: let the user decide which code need to be protected
  - ⇒ Need a way to tell the compiler what to apply and where!

# To the road of performances...

## Problem

- ▶ Impossible to apply all the obfuscations all the time
  - ▶ Locality: let the user decide which code need to be protected
- ⇒ Need a way to tell the compiler what to apply and where!

## In LLVM

- ▶ Function attributes to give hints to some optimisation passes
  - ▶ (De)activation of optimisations with flags / optimization level
  - ▶ But the compilation flow is "statically" written in the pass manager builder
- ⇒ No way to let the user specify the compilation flow!

# Pragma-based compilation flow

## Use pragma on code blocks/functions

```
#pragma global run_pass CallGraphFlat()

void foo(int) { ... }

#pragma run_pass OpaquePredicates(ratio=.9)
#pragma run_pass OpaqueZero()
int func_to_protect(int i)
{
    foo(0);
    return i*5;
}
```

Runs OpaqueZero and OpaquePredicates on func\_to\_protect, then CallGraphFlat on the whole module.

## Architecture

# Pragma-based compilation flow

## Use pragma on code blocks/functions

```
schedule:
- !function
  name: func_to_protect
  passes:
    - OpaqueZero()
    - OpaquePredicates(ratio=.9)
- !module
  passes:
    - CallGraphFlat()
```

Runs OpaqueZero and OpaquePredicates on func\_to\_protect, then CallGraphFlat on the whole module.

## Architecture

# Pragma-based compilation flow

## Use pragma on code blocks/functions

```
schedule:
- !function
  name: func_to_protect
  passes:
    - OpaqueZero()
    - OpaquePredicates(ratio=.9)
- !module
  passes:
    - CallGraphFlat()
```

Runs OpaqueZero and OpaquePredicates on func\_to\_protect, then CallGraphFlat on the whole module.

## Architecture

```
name: OpaquePredicates
level: basic block
options:
  - name: ratio
    values: [0.,1.]
```

# Pragma-based compilation flow

## Use pragma on code blocks/functions

```
schedule:
- !function
  name: func_to_protect
  passes:
    - OpaqueZero()
    - OpaquePredicates(ratio=.9)
- !module
  passes:
    - CallGraphFlat()
```

Runs `OpaqueZero` and `OpaquePredicates` on `func_to_protect`, then `CallGraphFlat` on the whole module.

## Architecture

- ▶ Custom pass factory to instantiate pass (and options) at runtime
- ▶ Creates and run classical `llvm::Pass`

# Table of Contents

Introduction

LLVM bitcode obfuscations

Frankenstein obfuscation

Improved pass management

User-defined compilation flow

LLVM pass ordering

Tests and benchmarks

## Compilation flow (simplified)

- ▶ LLVM optimisations passes
- ▶ **One** LLVM pass that schedules **obfuscations**
- ▶ **One** LLVM pass that schedules **post-optimize**

⇒ We run pass managers within an LLVM pass!

## Compilation flow (simplified)

- ▶ LLVM optimisations passes
- ▶ **One** LLVM pass that schedules **obfuscations**
- ▶ **One** LLVM pass that schedules **post-optimize**

⇒ We run pass managers within an LLVM pass!

## Is that really a good idea?

- ▶ Some optimisations rely on target dependant information (i.e.: `SimplifyLibCalls`)
- ▶ Where do they come from?

# Pass manager inception: gotcha

## Listing 1: clang/lib/CodeGen/BackendUtil.cpp:CreatePasses

```
Triple TargetTriple(TheModule->getTargetTriple());
std::unique_ptr<TargetLibraryInfoImpl> TLII(
    createTLII(TargetTriple, CodeGenOpts));
// [...]
MPM.add(new TargetLibraryInfoWrapperPass(*TLII));
// [...]
FPM.add(new TargetLibraryInfoWrapperPass(*TLII));
// [...]
PMBuilder.populateFunctionPassManager(FPM);
PMBuilder.populateModulePassManager(MPM);
```

## Gotcha

- ▶ TargetLibraryInfo and TargetTransformInfo analyzes must be forwarded to the new pass managers
- ▶ APIs of these analyzes isn't meant for this...
